***Abstract*—This report details the development of a role-based Airline Management System (AMS) designed to streamline flight operations and reservation processes. Built using Python, SQLite, and Tkinter, the system implements a robust architecture that distinguishes between passenger and administrative workflows. The application features automatic database initialization, integrity enforcement through SQL triggers, and a comprehensive data model. The results demonstrate an efficient, lightweight desktop solution for managing complex airline data relationships and transactional integrity.**

***Index Terms*—Airline Management, Python, SQLite, Tkinter, Database Design, Role-Based Access Control (RBAC).**

I. Introduction

The rapid growth of the aviation industry necessitates reliable software solutions to manage flight schedules, passenger reservations, and administrative oversight. The primary objective of this project is to develop a demo application that demonstrates realistic role separation in an airline environment. The system focuses on two distinct user paths: the Passenger flow, centered on flight discovery and booking, and the Admin flow, focused on operational management and request processing.

II. Technologies Used

The system architecture was selected based on the requirements for a lightweight, dependency-free, and rapid-development environment:

- **Python 3:** Served as the core application logic provider, handling the bridge between the GUI and the database.
- **SQLite:** Chosen for its serverless, file-based nature, allowing for easy deployment and zero-configuration setup.
- **Tkinter:** Utilized for the Graphical User Interface (GUI) to provide a native desktop experience without external library overhead.

III. Database Architecture and Initialization

A. Automatic Setup

A key feature of the system is the automatic initialization of the database. Upon the first execution, the application checks for the presence of `airline.db`. If missing, it executes `setup.sql` to generate the schema and load seed data.

B. Schema Structure

The relational schema consists of several core entities:

- **Users:** Stores credentials and role assignments (Passenger/Admin).
- **Flights:** Contains schedules, origins, destinations, and capacities.
- **Reservation_Requests:** Managed transactional data between users and flights.

C. Views and Triggers

To enhance performance and enforce business logic, the system utilizes:

- **v_flight_summary:** A view providing aggregated flight data for easy search.
- **v_request_overview:** A consolidated view for administrative review.
- **Triggers:** Automated rules to prevent duplicate seat assignments and overbooking beyond flight capacity.

IV. Roles and Workflows

A. Passenger Workflow

Passengers interact with a user-centric interface designed for efficiency:

- **Flight Search:** Filtering and listing available flights based on destination and time.
- **Booking:** Creating reservation requests including specific seat numbers and personal notes.
- **Tracking:** Monitoring the status (Pending/Approved/Rejected) of their requests.

B. Administrative Workflow

The Admin module provides high-level control over the system state:

- **Flight Management:** Full CRUD (Create, Read, Update, Delete) operations on flight schedules.
- **Request Processing:** Reviewing passenger requests with the ability to approve or reject based on operational criteria.
- **System Maintenance:** Managing demo users and auditing system logs.

V. ER Model Analysis

The Entity-Relationship (ER) model follows a highly normalized structure. It includes auxiliary entities such as **Countries, Airports, Routes, Airfare**, and **Airplane_Type**. This granular approach ensures data consistency and allows the system to scale with more complex attributes like multi-leg routes or tiered pricing models. The relationship between **Transactions** and **Auth_Accounts** ensures a clear audit trail for all financial and administrative actions.

Figure 1. Entity-Relationship Diagram (ERD) of the airline reservation and flight management system.

VI. Conclusion

The Airline Management System project successfully demonstrates the implementation of a role-based desktop application. By leveraging SQLite's trigger system and Python's logic handling, the application maintains high data integrity while providing a responsive user experience. Future iterations could include integration with external APIs for real-time weather tracking and more advanced seat mapping visualizations.
